Energy dynamics calculations in a 3D fluid simulation of drift wave turbulence in the linear Large Plasma Device [1] illuminate processes that drive and dissipate the turbulence. These calculations reveal that a nonlinear instability dominates the injection of energy into the turbulence by overtaking the linear drift wave instability that resides in the system of equations. The nonlinear instability drives flute-like $k_{\parallel} = 0$ density fluctuations through advection of the equilibrium density profile. Through nonlinear axial wavenumber transfer to $k_{\parallel} \neq 0$ fluctuations, the nonlinear instability accesses the adiabatic response, which provides the requisite energy transfer channel from density to potential fluctuations as well as the phase shift that causes instability. When the nonlinear instability is artificially removed from the system, the turbulence has a coherent frequency and wavenumber spectrum, which is inconsistent with experimental data, indicating that the nonlinear instability drives the plasma turbulence in the experiment.

PACS numbers:

I. INTRODUCTION

It is common practice to study a system's linear stability properties to gain insight into turbulent dynamics. It is often easier to calculate and analyze linear modes and growth rates than to simulate and analyze nonlinear turbulence. However, there are several situations in which linear properties can be misleading in understanding turbulent systems. First, linear studies that neglect stable branches of the linear dispersion relation often miss details of nonlinear dynamics. For example, stable eigenmodes can often impact nonlinear dynamics by providing energy sinks and sometimes energy sources not found on the most unstable linear branch [2–11]. Stable eigenmodes can shift the energy injection and dissipation ranges, making the turbulent dynamics very different from the Kolmogorov picture of hydrodynamic turbulence [12]. Second, systems with non-normal modes (non-orthogonal eigenvectors) display properties that are unexpected from linear calculations [9, 13]. In fact, systems with non-normal modes even make it difficult to predict dynamics when stable eigenmode branches are included in analyses. Third, linear stability analyses miss crucial nonlinear instability effects, which come in several varieties.

The most obvious variety of a nonlinear instability effect is that of subcritical turbulence in which no linear instabilities exist but turbulence is self-sustained given strong enough finite-amplitude perturbations. Subcritical turbulence is common in hydrodynamics [14], and although not as prevalent in plasma physics, several cases of subcritical plasma instabilities have been shown in the literature [15–20]. The second variety of nonlinear instability includes cases in which a particular linear instability is present in a system, but the turbulence is maintained by a nonlinear instability mechanism with different physical origin than the linear instability mechanism. This has been thoroughly explored in tokamak edge simulations in which linear ballooning instability drive is overtaken in the saturated phase by a nonlinear drift-wave drive [21–25]. Finally, it is often found that a particular linear instability is enhanced, depressed, and/or modified in the saturated phase by a nonlinear instability with a similar mechanism as the linear instability. In some of these cases nonlinear wavenumber transfers can increase or cause drive [26, 27], while in other cases zonal flow effects decrease drive [28, 29].

In order to avoid the pitfalls of relying too heavily on linear stability calculations in forming conclusions on turbulence characteristics, it is useful to diagnose turbulent simulations with energy dynamics analyses. Energy dynamics analyses track energy input into turbulent fluctuations and energy dissipation out of them. They also track conservative energy transfer between different energy types (e.g. from potential to kinetic energy) and between different scales, waves, or eigenmodes of a system. In this study, a two-fluid Braginskii model of turbulence in the Large Plasma Device (LAPD) is subjected to such an energy dynamics analysis. The result is that a nonlinear instability drives and maintains the turbulence in the steady state saturated phase of the simulation. While a linear resistive drift wave instability resides in the system, the nonlinear drift wave instability dominates when the fluctuation amplitude becomes large enough.

The nonlinear instability is identified by its energy growth rate spectrum, which varies significantly from the linear growth rate spectrum.

II. THE DRIFT WAVE MODEL

A Braginskii fluid model [30] is used to simulate drift wave turbulence in LAPD using the BOUT++ code [31]. The evolved variables used in the model are the plasma density, N , the electron fluid parallel velocity $v_{\parallel e}$, the potential vorticity $\varpi \equiv \nabla_{\perp} \cdot (N_0 \nabla_{\perp} \phi)$, and the electron temperature T_e . Cold ions are used, which eliminates ion temperature gradient drive, and sound wave effects are neglected. Details of the simulation and derivations of the model may be found in previous verification and validation studies [32–35], although electron temperature fluctuations were not included in those studies.

The equations appear with Bohm normalizations: lengths are normalized to ρ_s , times to ω_{ci}^{-1} , velocities to c_s , densities to the equilibrium peak density, and electron temperatures and potentials to the equilibrium peak electron temperature. The equations are:

$$\partial_t N = -\mathbf{v}_E \cdot \nabla N_0 - N_0 \nabla_{\parallel} v_{\parallel e} + \mu_N \nabla_{\perp}^2 N + S_N + \{\phi, N\}, \quad (1)$$

$$\partial_t v_{\parallel e} = -\frac{m_i}{m_e} \frac{T_{e0}}{N_0} \nabla_{\parallel} N + \frac{m_i}{m_e} \nabla_{\parallel} \phi - \nu_e v_{\parallel e} + \{\phi, v_{\parallel e}\}, \quad (2)$$

$$\partial_t \varpi = -N_0 \nabla_{\parallel} v_{\parallel e} - \nu_{in} \varpi + \mu_{\phi} \nabla_{\perp}^2 \varpi + \{\phi, \varpi\}, \quad (3)$$

$$\begin{aligned} \partial_t T_e = & -\mathbf{v}_E \cdot \nabla T_{e0} - 1.71 \frac{2}{3} T_{e0} \nabla_{\parallel} v_{\parallel e} + \frac{2}{3 N_0} \kappa_{\parallel e} \nabla_{\parallel}^2 T_e \\ & - \frac{2 m_e}{m_i} \nu_e T_e + \mu_T \nabla_{\perp}^2 T_e + S_T + \{\phi, T_e\}. \end{aligned} \quad (4)$$

In these equations, μ_N , μ_T , and μ_{ϕ} are artificial diffusion and viscosity coefficients used for subgrid dissipation. They are large enough to achieve saturation and grid convergence, but small enough to allow for turbulence to develop. In the simulations, they are all given the same value of 1.25×10^{-3} . This is the only free parameter in the simulations. All other parameters such as the electron collisionality ν_e , ion-neutral collisionality ν_{in} , parallel electron thermal conductivity $\kappa_{\parallel e}$, and mass ratio $\frac{m_i}{m_e}$ are calculated from the experimental values. There are two sources of free energy: the density gradient due to the equilibrium density profile N_0 , and the equilibrium electron temperature gradient in T_{e0} , both of which are taken from experimental fits. N_0 and T_{e0} are only functions of the distance from the axis r .

The terms in Poisson brackets are the advective nonlinearities, which are the only nonlinearities used in the simulations. The numerical simulations are fully spatial in all three dimensions (as opposed to spectral) and use cylindrical annular geometry ($12 < r < 40 \text{ cm}$). The simulations use periodic boundary conditions in the axial (z) direction and Dirichlet boundary conditions in the radial (r) direction for the fluctuating quantities.

Simulations also use density and temperature sources (S_n and S_T) in order to keep the equilibrium profiles from relaxing away from their experimental shapes. These sources subtract out the azimuthal averages ($m = 0$ component of the density and temperature fluctuations) at each time step. Zonal flows are allowed to form and evolve. The parallel current, which is often found explicitly in these equations is replaced here by $J_{\parallel} = -N_0 v_{\parallel e}$.

Some basic statistical properties of the density fluctuations of the simulation are shown in Fig. 1 compared to the corresponding results from the experiment on which this simulation is based. The simulation reproduces these statistical properties with relatively good qualitative and quantitative accuracy.

III. ENERGETICS MACHINERY

The expression for the normalized energy of the wave fluctuations in the drift wave model is:

$$E = \frac{1}{2} \int_V (N^2 + \frac{3}{2} T_e^2 + \frac{m_e}{m_i} v_{\parallel e}^2 + N_0 (\nabla_{\perp} \phi)^2) dV. \quad (5)$$

The N^2 contribution is the potential energy due to density fluctuations, $\frac{3}{2} T_e^2$ is the electron temperature fluctuation potential energy, $\frac{m_e}{m_i} v_{\parallel e}^2$ is the parallel electron kinetic energy, and $N_0 (\nabla_{\perp} \phi)^2$ is the $E \times B$ perpendicular kinetic energy. These energies are conserved individually by their respective advective nonlinearities.

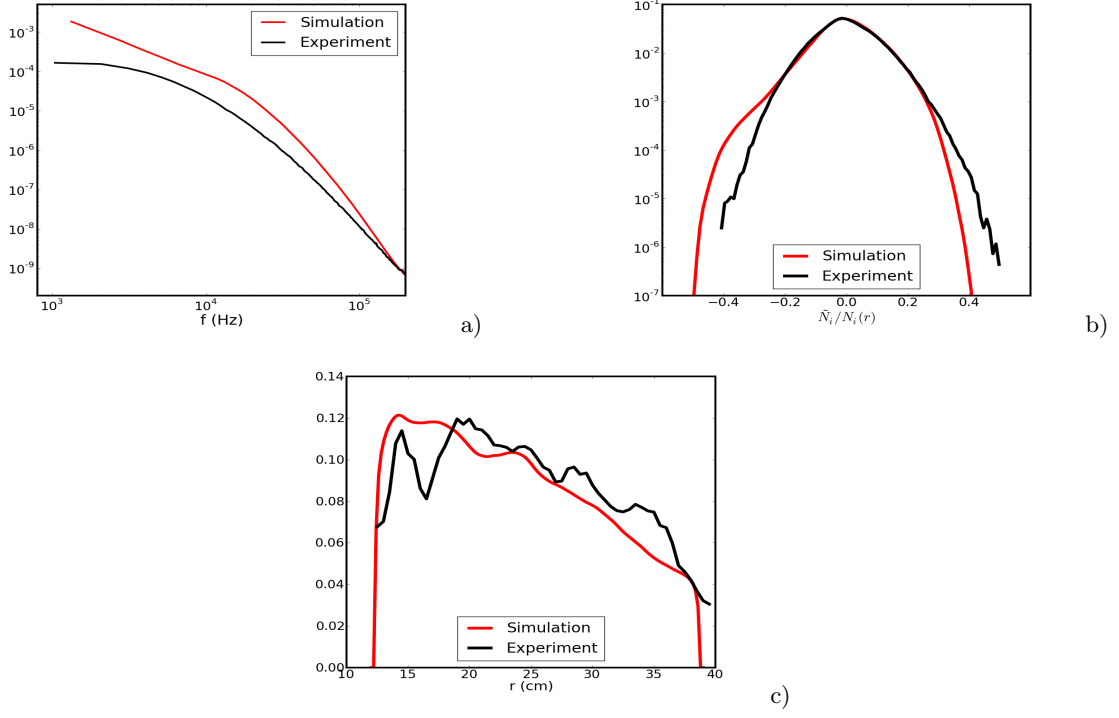

FIG. 1: **a)** The power spectral density of the density fluctuations, showing the results from simulation versus experiment, **b)** the probability distribution function of the density fluctuations, and **c)** the RMS amplitude of the density fluctuations as a function of radius.

It is most instructive to analyze the spectral energy dynamics rather than the total energy dynamics. To do this, each field at a given time is Fourier decomposed as $f(r, \theta, z) = \sum_k f_k(r) e^{i(m\theta + k_z z)}$, where the subscript k represents the spectral wavenumbers, (m, n) . m is the azimuthal wavenumber while n is the axial integer wavenumber such that $k_z = \frac{2\pi n}{l_z}$. Note that the radial direction is not spectrally decomposed because the radial dependence of the profiles and differential operators complicates the analysis. Then, the energy of each Fourier $k = (m, n)$ mode is

$$E_{tot}(k) = \frac{1}{2} \left\langle |n_k|^2 + \frac{3}{2} |t_k|^2 + \frac{m_e}{m_i} |v_k|^2 + N_0 \left| \frac{\partial \phi_k}{\partial r} \right|^2 + N_0 \frac{m^2}{r^2} |\phi_k|^2 \right\rangle, \quad (6)$$

where the brackets $\langle \rangle$ represent the radial integral: $\int_{r_a}^{r_b} r dr$. The energy evolution for each Fourier mode of each field has the form:

$$\frac{\partial E_j(k)}{\partial t} = Q_j(k) + C_j(k) + D_j(k) + \sum_{k'} T_j(k, k'). \quad (7)$$

The index j stands for each field, (n, t, v, ϕ) , and the sum over j gives the total energy evolution. Note that with the conventions used, the symbol n denotes both the axial mode number as well as the Fourier coefficient of the density fluctuation. The differences should be clear in context. The derivation of equation 7 is given in the appendix along with the full expressions for each of the parts. $T_j(k, k')$ is the nonlinear energy transfer function that comes from the advective nonlinearities. It describes the nonlinear energy transfer rate of modes $k' = (m', n')$ and $k - k' = (m - m', n - n')$ to the mode $k = (m, n)$. In other words, a positive value of $T_j(k, k')$ indicates that fluctuations at wavenumber k gain energy from gradient fluctuations at wavenumber k' and flow fluctuations at wavenumber $k - k'$. When summed over k' as in equation 7, the result is the total nonlinear energy transfer into mode k . Note that $\sum_{k, k'} T_j(k, k') = 0$ because the nonlinearities conserve energy individually in each of equations 1-4. This is easily proven by the following identity:

$$\int_{\Omega} q\{p, q\} d\Omega = \int_{\Omega} p\{p, q\} d\Omega = 0, \quad (8)$$

which holds when boundary conditions are periodic or zero value as they are in the simulation. The fact that the advective nonlinearities conserve energy means that they can transfer energy between different Fourier waves, but they cannot change the energy of the volume-averaged fluctuations as a whole. Only the linear terms do this. Other possible nonlinearities that do not conserve energy are not included in the model equation set or in simulations. Furthermore, it is important that the simulations employ an energy conserving finite difference scheme for the advective nonlinearities, and most common numerical advection schemes do not have this property. Therefore, an Arakawa advection scheme [36] that conserves energy of the advected quantity is used for the nonlinear advection terms in the simulations.

The linear terms in equations 1-4 do not conserve energy individually or as a whole. The linear terms are broken up into three contributions in equation 7. $D_j(k)$ represents nonconservative energy dissipation due to collisions, artificial diffusion and viscosity, and the purely dissipative density and temperature sources. Each contribution to $D_j(k)$ is negative, and the exact expressions are given in the appendix. $C_j(k)$ contains the linear terms dubbed “transfer channels” [23]. They are rewritten here:

$$C_n(k) = \text{Re} \{ \langle -ik_z N_0 v_k n_k^* \rangle \} \quad (9)$$

$$C_v(k) = \text{Re} \{ \langle -ik_z N_0 n_k v_k^* + ik_z N_0 \phi_k v_k^* - 1.71 ik_z T_{e0} t_k v_k^* \rangle \} \quad (10)$$

$$C_\phi(k) = \text{Re} \{ \langle ik_z N_0 v_k \phi_k^* \rangle \} \quad (11)$$

$$C_t(k) = \text{Re} \{ \langle -1.71 ik_z T_{e0} v_k t_k^* \rangle \} \quad (12)$$

Notice that $C_n(k) + C_v(k) + C_\phi(k) + C_t(k) = 0$, which is most clearly seen upon conjugation of $C_v(k)$ inside the real part operator. This is the reason why these terms are called transfer channels. They represent the transfer between the different types of energy of the different fields ($N, \phi, T_e \leftrightarrow v_{\parallel e}$), but taken together, they do not create or dissipate total energy from the system. The only energy field transfer in this system occurs through the parallel electron velocity (parallel current) dynamics. There is no direct transfer between the state variables N, ϕ , and T_e . Altogether, the coupling through the parallel current is called the adiabatic response. It is an essential part of both the linear and nonlinear drift wave mechanisms [23, 25]. The adiabatic response moves energy from the pressure fluctuations to the perpendicular flow through the parallel current.

Finally, the $Q_j(k)$ terms represent the nonconservative energy sources. They are rewritten here:

$$Q_n(k) = \text{Re} \left\{ \left\langle -\frac{im}{r} \partial_r N_0 \phi_k n_k^* \right\rangle \right\} \quad (13)$$

$$Q_v(k) = \text{Re} \left\{ \left\langle ik_z \frac{N_0^2 - T_{e0}}{N_0} n_k v_k^* + ik_z (1 - N_0) \phi_k v_k^* + 1.71 ik_z (T_{e0} - 1) t_k v_k^* \right\rangle \right\} \quad (14)$$

$$Q_\phi(k) = 0 \quad (15)$$

$$Q_t(k) = \text{Re} \left\{ \left\langle -\frac{3}{2} \frac{im}{r} \partial_r T_{e0} \phi_k t_k^* \right\rangle \right\} \quad (16)$$

$Q_n(k)$ is the energy extraction from the equilibrium density profile into the density fluctuations. This term may have either sign depending on the phase relation between ϕ_k and n_k , so it can in fact dissipate fluctuation potential energy from the system as well as create it at each k . $Q_t(k)$ is completely analagous to $Q_n(k)$ but for the temperature rather than the density. $Q_v(k)$ is parallel kinetic energy extraction or dissipation, which is a rather unphysical, but fortunately insignificant term. The source of these terms are the equilibrium gradients, which is evident because if the profiles were flat ($N_0 = T_{e0} = 1$), all $Q(k)$ would vanish. Moreover, the particular normalization of equations 1-4 combined with the choice of energy definition (equation 5) causes the non-zero $Q_v(k)$, which again is quite insignificant.

IV. NONLINEAR ENERGY DYNAMICS

A. Energy Spectra

Fig. 2 shows the time evolution of the total energy of the fluctuations. The simulation starts with a random initial perturbation, and the fluctuations grow exponentially until reaching saturation. All analysis of the saturated (turbulent) stage is done by averaging over the time steps from 100-235 (note that these are just output time steps, while there are tens of thousands of explicitly evolved states in between each of these output steps). The turbulent spectral energy, defined in equation 6 is shown in Fig. 3. The energy is broken up into its different types (e.g.

FIG. 2: Time evolution of the volume-averaged total energy. Each time step is $400/\omega_{ci} \sim 170\mu s$

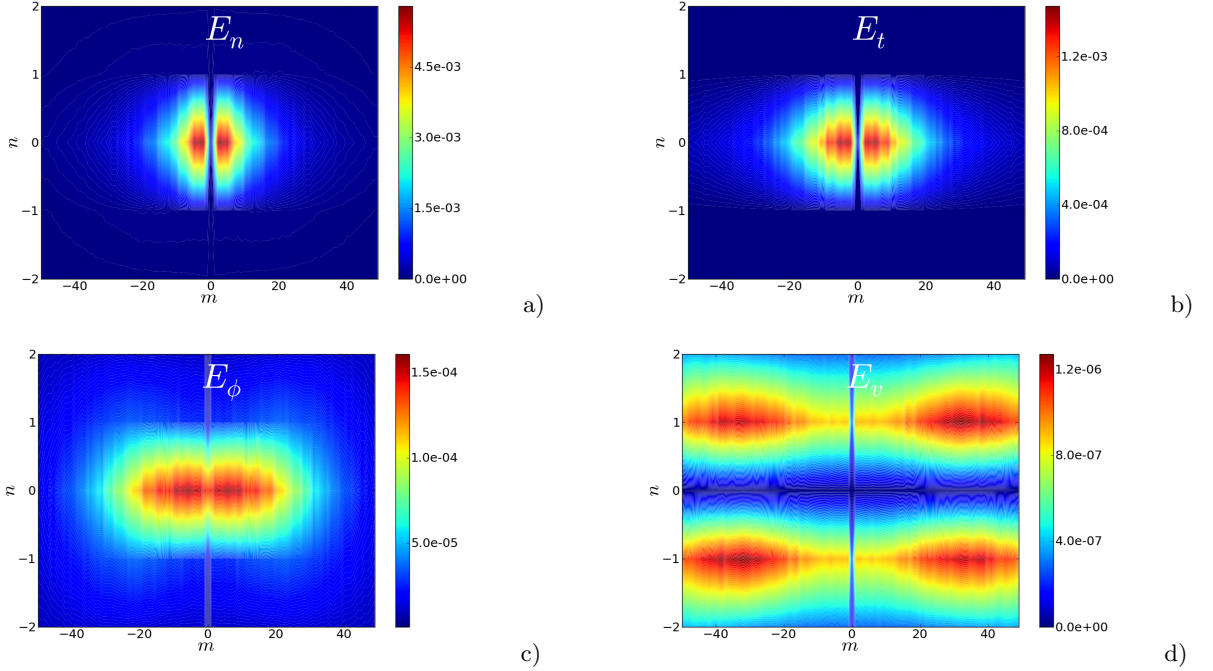

FIG. 3: **a)** $E_n(k)$, **b)** $E_t(k)$, **c)** $E_\phi(k)$, and **d)** $E_v(k)$ in the $m - n$ plane averaged over time during the saturated turbulent phase. Note the different scales used on each figure.

perpendicular kinetic energy: E_ϕ). There are a few clear nonlinear properties seen in these figures. The first is that the energy is located in different spectral regions for the different energy types. This has to be a nonlinear effect because the linear eigenmodes are Fourier modes in the azimuthal and axial directions and all fields grow at the same rate for an eigenmode. Another property unexpected from linear stability analysis is that the majority of the potential and perpendicular kinetic energy (E_n , E_t , and E_ϕ) is contained in $n = 0$ structures, which are often called flute modes. This is unexpected because there is no $n = 0$ linear instability present in the system, which has been confirmed by eigenvalue calculations. The only linear instability of the system is the linear resistive drift wave instability, which requires finite n to provide the phase shift and state variable coupling to drive the waves unstable. Perhaps equally unexpected is the complete lack of parallel kinetic energy in the $n = 0$ range. The E_v spectrum looks like a traditional linear drift wave spectrum, but does not correspond to the other fields, which is atypical of linear drift waves.

FIG. 4: Diagram of the nonlinear instability process that drives convective cells.

B. Description and Evidence for the Nonlinear Instability

Now, the flute mode dominance has to be a nonlinear effect because linear drift waves require finite n . However, the cause of the flute dominance is not simple cascade dynamics, a secondary instability, nor a potential-driven flute-like instability such as Kelvin-Helmholtz or interchange. The cause is a primary nonlinear instability like that described in [17, 26]. This nonlinear instability is a multi-step process that is outlined in Fig. 4. In the first step, $n = 0$ density and potential fluctuations *nonconservatively* draw energy from the equilibrium density gradient as prescribed by $Q_n(m, n = 0)$ defined in equation 13, and feed this energy into the $n = 0$ density fluctuations only. The nonconservative linear terms, after all, can only inject, dissipate, or transfer energy at one wavenumber at a time, so it takes $n = 0$ fluctuations to nonconservatively inject energy into $n = 0$ fluctuations. Note also that the temperature fluctuations work in the same way as the density fluctuations, and one could replace $n(m, n)$ (the spectral density component) with $t(m, n)$ (the spectral temperature component) in the diagram. The density and temperature are analogous and work in parallel, however the temperature fluctuations are a few times smaller than the density fluctuations and provide weaker drive because parallel heat conduction strongly dissipates the temperature fluctuations, which is why the diagram highlights the density contribution. This was also previously observed [22]. In the second step of the diagram, these $n = 0$ density fluctuations *conservatively* transfer energy to $n \neq 0$ density fluctuations by the nonlinear $T_n(k, k')$ transfer process. The third step involves the transfer at finite n from the density fluctuations to the potential fluctuations by way of the parallel current in the adiabatic response. The $C_j(k)$ terms describe this adiabatic response. Fourth and finally, the $T_\phi(k, k')$ interaction conservatively transfers energy from $n \neq 0$ to $n = 0$ potential ϕ fluctuations in inverse fashion, at which point the process starts over.

The evidence for this mechanism is best shown with help from the energy dynamics machinery derived in section III. Fig. 5 summarizes the effects of the nonconservative linear terms, which are fully responsible for injecting energy into the fluctuations. Fig. 5a shows the E_n dynamics separated into different parallel wavenumbers and plotted against the azimuthal wavenumber m . Clearly, most of the energy is injected into $n = 0$ density structures, while only a small amount of energy is injected into $n = \pm 1$ structures despite the fact that the linear instability is active only at $n \neq 0$. The large positive $Q_n + D_n$ (injection plus dissipation) at $n = 0$ provides evidence for the first step of the diagram in Fig. 4. Note however, that the dissipation from the source, which acts entirely at $m = 0$ is not shown in this figure, but is rather large. Modes with $n \geq 2$, on the other hand, play a negligible role in density injection, dissipation, and transfer. Furthermore, all of the net energy injected into the density fluctuations ($Q_n + D_n$) is transferred out (C_n) to the parallel current (electron velocity), which only occurs at finite n , almost entirely at $n = \pm 1$. The net change of E_n , which is the sum $Q_n + D_n + C_n$ over all m and n is approximately zero because this analysis is averaged over the steady state turbulence, although this is not so evident in Fig. 5a without the source dissipation. The necessary balance implies, as will be proven later, that the nonlinearities transfer energy from $n = 0$ to $n = \pm 1$ modes, where that energy can then be transferred to the parallel current.

Fig. 5b shows the temperature potential energy dynamics. Again flute structures inject energy into the fluctuations, but unlike in the density case, $n = \pm 1$ modes dissipate more energy than they inject. Moreover, the small value of C_t reveals that the temperature fluctuations inject only a small amount of energy into the parallel current compared to the density fluctuations. Despite the fact that the equilibrium temperature gradient is quite a bit steeper than the density gradient, its free energy is not used efficiently by the waves in the sense that it is largely dissipated before being transferred to the electrostatic potential. The reason for the difference between the density and temperature responses is the extra dissipation routes for the temperature fluctuations, namely, the parallel heat conduction and electron-ion heat exchange. One should therefore be careful in assuming that adding free energy sources to an analysis

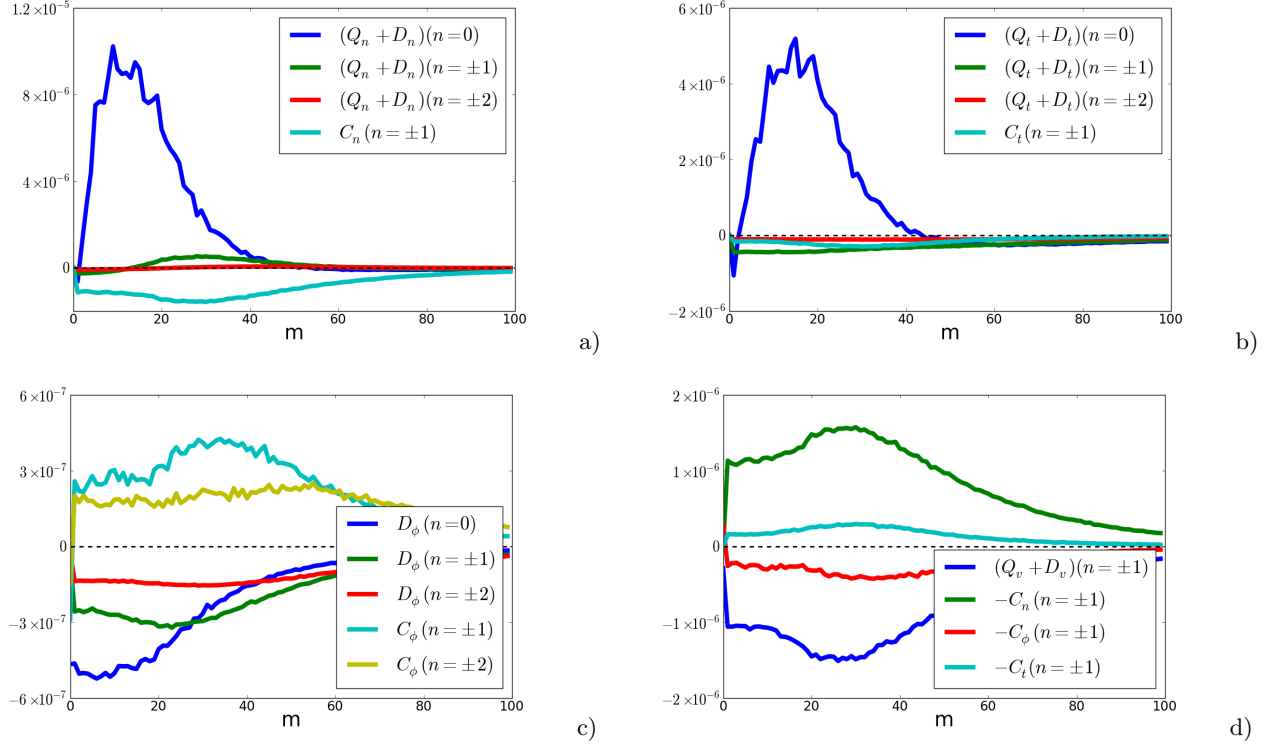

FIG. 5: **a)** The solid curves quantify the energy dynamics of the density potential energy averaged over time during the saturated turbulent phase. The notation $n \pm 1$ represents the summation over the $n = 1$ and $n = -1$ curves. **b)** The energy dynamics of the temperature potential energy, **c)** the perpendicular kinetic energy, and **d)** the parallel dynamics (adiabatic response). The contributions to $C_v(k)$ in **d)** are broken up with $C_v(k) = -C_n(k) - C_t(k) - C_\phi(k)$. The density and temperature sources are neglected in **a)** and **b)** respectively. They only contribute at $m = 0$.

will automatically increase instability drive. The same type of result was seen in a study of tokamak edge turbulence [22], although there, the temperature fluctuations were even more dissipative than in this study in that they actually drew energy from the parallel current.

Next, Fig. 5c illustrates the perpendicular kinetic energy dynamics provided by the electrostatic potential ϕ . Since there is no free energy source for the potential ($Q_\phi = 0$), the potential fluctuations derive their energy from the parallel current through the C_ϕ transfer channel, which is positive everywhere and only finite for finite n . Otherwise, ion-neutral collisions and viscosity dissipate energy from the potential fluctuations as shown by the D_ϕ curves. An interesting detail seen in this figure is that modes with $|n| > 1$ actually contribute to the transfer channel and dissipation, whereas these modes are negligible for the other fields.

The last piece, the parallel dynamics, also called the adiabatic response, is displayed in Fig. 5d. The primary effect of the adiabatic response is to take energy from the density fluctuations and transfer it to the potential fluctuations, which only occurs at finite parallel wavenumber. This effect corresponds to the third step in Fig. 4. Moreover, resistivity dissipates a fair portion of this parallel kinetic energy, and although not evident from this figure, provides the primary phase shift mechanism between the density and potential that allows for instability. The temperature fluctuations also provide energy to the potential fluctuations through this response, although it is much weaker than the density fluctuation route.

Steps 2 and 4 in Fig. 4 come not from the nonconservative linear terms in the equations, but from the conservative nonlinear advective terms. The interactions described by the advective nonlinearities are in the nonlinear transfer functions: $T_j(k, k')$ in equation 7. The difficulty in looking at the $T_j(k, k')$ functions is that they are four dimensional functions of (m, n, n', m') , which makes complete visualization impossible. It is therefore convenient to sum over various transfers or look at specific wavenumber transfers of interest. The most easily decipherable results that compliment the results of Fig. 5 are shown in Fig. 6. First, Fig. 6a sums the transfer functions over (n, m', n') , leaving only a function of m , which illustrates the aggregate azimuthal mode number transfers. Note that the sum of each individual curve over m is zero because the nonlinearities are conservative. Positive values in Fig. 6a indicate energy transfer into structures with azimuthal mode number m , while negative values indicate energy transfer out of

FIG. 6: **a)** Conservative nonlinear energy transfer functions $T_j(k, k')$ summed over k' and n . The line labeled ϕ represents the function $\sum_{k', n} T_\phi(k, k')$, which is a function of m . **b)** Transfer functions summed over k' and m . Note that $T_v(k, k')$ is multiplied by 20 in both figures to make it visibly different from zero.

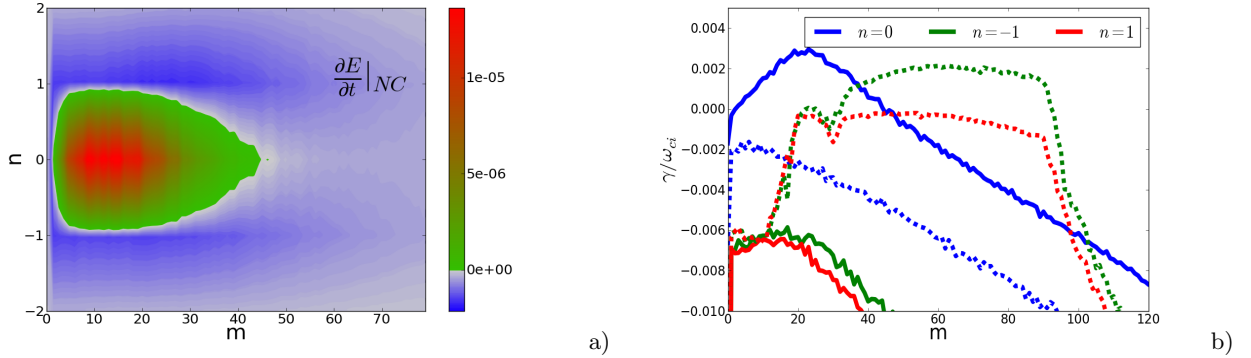

FIG. 7: **a)** The total spectral nonconservative energy injection $\frac{\partial E(k)}{\partial t}|_{NC}$ and **b)** the spectral nonconservative growth rate spectrum $\gamma_T(k)$ of the turbulence compared to the linear growth rate spectrum, $\gamma_L(k)$. The solid lines represent $\gamma_T(k)$ which is calculated using equation 17 averaged over the saturated turbulent phase, while the dashed lines represent $\gamma_L(k)$ and are calculated with the same equation using the linear phase of the simulation.

structures with corresponding mode number m . The density and temperature nonlinearities are qualitatively similar in that they cause both forward and inverse transfer out of the wavenumbers that nonconservatively inject the most energy. The potential (polarization) and parallel velocity nonlinearities cause inverse transfer to low wavenumbers.

Fig. 6b displays the conservative transfers summed over (n, m', n') , leaving only a function of m , which describes transfer into and out of different parallel modes. This is the figure which provides evidence for steps 2 and 4 of the instability diagram. Now, as expected from step 2 of the diagram and foreshadowed by Fig. 5b, density potential energy is aggregately transferred from $n = 0$ convective cells into $n \neq 0$ modes, specifically $n = \pm 1$. This can be called a direct transfer in analogy with the terminology used for hydrodynamic wavenumber cascades. The temperature fluctuations have the same transfer tendency as the density fluctuations, while the parallel velocity exhibits direct transfer, although from $n = 1$ to higher modes since there is never any $n = 0$ energy in the parallel velocity. The potential fluctuations, on the other hand, exhibit inverse parallel wavenumber transfer (step 4 of the diagram), populating $n = 0$ potential structures. This nonlinear transfer is the only way to drive energy into $n = 0$ potential structures because $Q_\phi = 0$. That completes the evidence for the nonlinear instability picture along with further details of both the conservative and nonconservative energy dynamics.

C. The Global Injection and Dissipation Picture

The details of the energy dynamics given above are important but can obstruct the most significant results. Specifically, Fig. 5 contains a lot of details that can be contracted by summing over the different energy types. Fig. 7 does this, showing the total spectral nonconservative energy dynamics. Fig. 7a, which is a plot of the nonconservative rate

FIG. 8: **a)** The turbulent growth rate spectrum $\gamma_T(k)$ with $n = 0$ density and potential components removed from the simulation compared to the linear growth rate spectrum $\gamma_L(k)$. **b)** The solid lines are the same $\gamma_T(k)$ spectrum as the solid lines in (a), but the dashed lines are the turbulent growth rate spectrum when the zonal flows are retained in the simulation.

of change of the total energy, $\frac{\partial E(k)}{\partial t}|_{NC} = \sum_j Q_j(k) + C_j(k) + D_j(k)$, reveals a global picture in wavenumber space of where the total energy is injected into the system and where it is dissipated. Namely, energy injection occurs on average at $(n = 0, 3 < m < 45)$, while it is dissipated everywhere else including at $n = \pm 1$ for all m . It is obvious that the nonlinear wavenumber transfers must take energy from the injection region to the dissipation region, and that is consistent with what was shown in Fig. 6. This further reveals a picture quite different than what one would expect from the standard picture of plasma turbulence in which energy is injected where the *linear* growth rate is positive and dissipated where it is negative. To clarify this point, the linear $\gamma_L(k)$ versus turbulent growth rate $\gamma_T(k)$ spectra are shown in Fig. 7b. The growth rates are calculated using

$$\gamma(k) = \left(\sum_j Q_j(k) + C_j(k) + D_j(k) \right) / \left(2 \sum_j E_j(k) \right). \quad (17)$$

The turbulent growth rate spectrum, simply means that equation 17 is calculated using the terms from the saturated turbulent phase of the simulation. Note that the linear growth rate is positive for $(n = -1, 35 < m < 95)$ and negative everywhere else. The turbulent growth rate is positive only for $(n = 0, 3 < m < 45)$. The linear and turbulent spectral injection regions do not even overlap. Seemingly, the linear physics is completely washed out in the turbulent state. More than anything, the turbulent growth rate spectrum reveals how robust the linear physics is in the turbulent state.

V. LINEAR VS NONLINEAR INSTABILITY DRIVE

Although the nonlinear flute mode dynamics present a clear case of nonlinear instability, the $n \neq 0 \leftrightarrow n = 0$ energy path is not a necessary feature of nonlinear drift wave instabilities, which is clear in tokamak studies of drift wave turbulence [21–25]. Furthermore, the periodic axial boundary conditions used in the LAPD turbulence simulation which allow for axial Fourier eigenmodes (including those with $n = 0$) are obviously unphysical.

Eliminating the ideal flute structures is then instructive in determining how robust the nonlinear instability is in this instance of drift wave turbulence. There are a few ways to eliminate the flute modes in the simulation such as eliminating one of the nonlinearities that is essential to the nonlinear instability process described in Fig. 4. However, simply subtracting out the $n = 0$ components of the density and potential at each simulation time step retains more of the physics that may be essential to cause nonlinear instability. The results of such a simulation are shown in Fig. 8. Interestingly, the turbulent growth rate spectrum $\gamma_T(k)$ is nearly identical to the linear growth rate spectrum $\gamma_L(k)$, as seen in Fig. 8a. It is noted that subtracting out the $n = 0$ potential component removes the zonal flow ($m = n = 0$) from the system, providing a possible explanation for the large change in behavior of the turbulent growth rate spectrum. However, this hypothesis is dispelled by the analysis of a simulation in which only the $n = 0, m \neq 0$ potential components are removed while the zonal flow is left intact. The growth rate spectrum of this simulation, shown in Fig. 8b, reveals that the zonal flow plays a minimal role in the nonlinear instability dynamics. The zonal flow simply decreases the growth rates by a small amount, causing no change to the qualitative picture.

FIG. 9: Comparison of the frequency spectra. Notice the spectra with $n = 0$ components removed is not broadband, but has a clear peak, which is inconsistent with experiment.

Therefore, the flute modes are necessary for a nonlinear instability to overtake the linear instability in driving the turbulence. In other words, a 2D simplification using a fixed parallel wavelength does not support a nonlinear instability in this case. Now, one indication that the nonlinear instability is important in reproducing experimentally consistent turbulence is that the turbulence of the simulation with the $n = 0$ components removed becomes overly coherent. This can be seen in the wavenumber or frequency spectrum. The frequency spectrum is shown in Fig. 9 compared with the experimental spectra and the spectra of the standard nonlinear instability dominated simulation. The clear peak in the spectra of the $n = 0$ removed simulation is inconsistent with experiment, indicating that something in the standard simulation – possibly the nonlinear instability – is important for reproducing experimentally relevant turbulence. A more direct test with realistic axial boundary conditions is left for a future study.

VI. CONCLUSION

In contrast to experiments, simulations provide vast quantities of spatial information, and can therefore be useful in illuminating physical processes responsible for driving and saturating turbulence. It is possible to get more than fluctuation levels, flux values, diffusivities, and spectra from simulations. The kind of energy analysis used in this study is one way in which detailed physics can be drawn from a turbulence simulation. Here, energy dynamics analysis shows a complex picture of turbulent energy injection, transfer, and dissipation. Such a picture was certainly not evident *a priori*. Other more advanced procedures such as eigenmode decompositions [2] or proper orthogonal decompositions (POD) [11], which are extensions of this procedure, can reveal even more physical processes, especially those involving saturation.

In this study, however, a partial spectral decomposition and energy dynamics analysis was sufficient to reveal the dominance of a nonlinear instability in driving and maintaining the turbulence. This particular nonlinear instability relies upon flute mode creation, axial wavenumber transfer, and the adiabatic response, but these features are not universal for nonlinear plasma instabilities. Nevertheless, understanding nonlinear instabilities is important because they can invalidate the use of quasilinear flux estimates and linear mixing length arguments of diffusion levels when linear instabilities are insignificant in the turbulent state. Simple rules for when nonlinear instabilities will act or overtake linear ones are needed, and one attempt at such a rule is made in [25] for drift wave turbulence. That rule states that nonlinear instabilities will overtake linear instabilities when $\gamma_L < \omega_*$, which is true for the parameters used in this study. However, more study of this rule and others is warranted, and will be important as long as linear calculations are used to inform predictions of turbulence. Nevertheless, full nonlinear simulations and energy dynamics analyses should be performed whenever possible to obtain details of plasma turbulence mechanisms.

Acknowledgments

This research was performed under appointment to the Fusion Energy Sciences Fellowship Program administered by Oak Ridge Institute for Science and Education under a contract between the U.S. Department of Energy and the Oak Ridge Associated Universities. We would also like to thank Paul Terry for many useful discussions on this topic.

APPENDIX A: EXPLICIT CALCULATION OF THE ENERGY EVOLUTION OF A FOURIER MODE

The energy evolution for each Fourier wave mode can be obtained by Fourier decomposing each of equations 1 - 4 and then multiplying the density, electron parallel velocity, vorticity, and electron temperature equations by the complex conjugates of the density, velocity, potential, and temperature respectively, and integrating over space. Adding the resulting equations gives the energy evolution of each Fourier mode.

Take the density equation as an example for this procedure. The decomposition for the density is:

$$N(r, \theta, z, t) = \sum_k n_k(r, t) e^{i(m\theta + k_z z)}. \quad (A1)$$

Recall that the subscript k is short for (m, n) as the decomposition is a 2D Fourier decomposition in the azimuthal and axial directions, making the sum over k truly a double sum over m and n . Furthermore, positive and negative m and n are included in the sums to ensure reality of N , which also requires that $n_{-k} = n_k^*$. Similar decompositions are used for $v_{\parallel e}$ and ϕ . The density source is azimuthally symmetric, so it is decomposed as:

$$S_N(r, z, t) = \sum_{k_z} S_{Nk_z}(r, t) e^{ik_z z}. \quad (A2)$$

Substituting this decomposition into equation 1 gives:

$$\begin{aligned} \sum_k \frac{\partial n_k}{\partial t} e^{i(m\theta + k_z z)} &= \sum_{k_z} S_{Nk_z} e^{ik_z z} + \\ \sum_k \left[-\frac{im}{r} \partial_r N_0 \phi_k - ik N_0 v_k + \mu_N (\partial_r^2 n_k + \frac{1}{r} \partial_r n_k - \frac{m^2}{r^2} n_k) \right] e^{i(m\theta + k_z z)} \\ &+ \frac{1}{r} \sum_{k, k'} (im n_k \partial_r \phi_{k'} - im' \partial_r n_k \phi_{k'}) e^{i(m+m')\theta + i(k_z + k'_z)z}. \end{aligned} \quad (A3)$$

Multiplying through by $n_{k''}^* e^{-im''\theta - ik''z}$ and integrating over space (and permutting primes) gives:

$$\begin{aligned} \left\langle \frac{\partial n_k}{\partial t} n_k^* \right\rangle &= \langle S_{Nk_z} n_{m=0, k_z}^* \rangle \\ \left\langle -\frac{im}{r} \partial_r N_0 \phi_k n_k^* - ik N_0 v_k n_k^* + \mu_N (\partial_r^2 n_k + \frac{1}{r} \partial_r n_k - \frac{m^2}{r^2} n_k) n_k^* \right\rangle \\ &+ \left\langle \frac{1}{r} \sum_{k'} (im' n_{k'} \partial_r \phi_{k-k'} n_k^* - i(m-m') \partial_r n_{k'} \phi_{k-k'} n_k^*) \right\rangle. \end{aligned} \quad (A4)$$

Finally, taking the real part of this equation results in:

$$\begin{aligned} \left\langle \frac{1}{2} \frac{\partial |n_k|^2}{\partial t} \right\rangle &= Re \{ \langle S_{Nk_z} n_{m=0, k_z}^* \rangle \} \\ Re \left\{ \left\langle -\frac{im}{r} \partial_r N_0 \phi_k n_k^* - ik N_0 v_k n_k^* + \mu_N (\partial_r^2 n_k + \frac{1}{r} \partial_r n_k - \frac{m^2}{r^2} n_k) n_k^* \right\rangle \right\} \\ &+ Re \left\{ \left\langle \frac{1}{r} \sum_{k'} (im' n_{k'} \partial_r \phi_{k-k'} n_k^* - i(m-m') \partial_r n_{k'} \phi_{k-k'} n_k^*) \right\rangle \right\}. \end{aligned} \quad (A5)$$

Note that taking the real part of the equation produces the expected energy-like term on the left hand side because:

$$\frac{1}{2} \frac{\partial |n_k|^2}{\partial t} = Re \left\{ \frac{\partial n_k}{\partial t} n_k^* \right\}. \quad (A6)$$

Breaking the result into explicit parts:

$$\frac{\partial E_n(k)}{\partial t} = Q_n(k) + C_n(k) + D_n(k) + \sum_{k'} T_n(k, k') \quad (\text{A7})$$

$$E_n(k) = \frac{1}{2} \langle |n_k|^2 \rangle \quad (\text{A8})$$

$$Q_n(k) = \text{Re} \left\{ \left\langle -\frac{im}{r} \partial_r N_0 \phi_k n_k^* \right\rangle \right\} \quad (\text{A9})$$

$$C_n(k) = \text{Re} \{ \langle -ik N_0 v_k n_k^* \rangle \} \quad (\text{A10})$$

$$D_n(k) = \text{Re} \left\{ \left\langle \mu_N (\partial_r^2 n_k + \frac{1}{r} \partial_r n_k - \frac{m^2}{r^2} n_k) n_k^* + S_{Nk_z} n_{m=0, k_z}^* \right\rangle \right\} \quad (\text{A11})$$

$$T_n(k, k') = \text{Re} \left\{ \left\langle \frac{1}{r} (im' n_{k'} \partial_r \phi_{k-k'} n_k^* - i(m-m') \partial_r n_{k'} \phi_{k-k'} n_k^*) \right\rangle \right\} \quad (\text{A12})$$

$Q_n(k)$ is the source, $C_n(k)$ is the transfer channel, $D_n(k)$ is dissipation, and $T_n(k, k')$ is spectral energy transfer. The same type of procedure may be applied to equations 2-4. However, the double primed conjugate multiplications (as in the step between equations A3 and A4) must be done with the Fourier fields, $\frac{m_e}{m_i} v_{k''}$, $-\phi_{k''}$, and $\frac{3}{2} t_{k''}$ rather than $v_{k''}$, $\varpi_{k''}$, and $t_{k''}$. These produce the correct energy terms, and most importantly still conserve the nonlinearities. The corresponding expressions for the perpendicular kinetic energy are:

$$\frac{\partial E_\phi(k)}{\partial t} = Q_\phi(k) + C_\phi(k) + D_\phi(k) + \sum_{k'} T_\phi(k, k') \quad (\text{A13})$$

$$E_\phi(k) = \frac{1}{2} \left\langle N_0 \left| \frac{\partial \phi_k}{\partial r} \right|^2 + N_0 \frac{m^2}{r^2} |\phi_k|^2 \right\rangle \quad (\text{A14})$$

$$Q_\phi(k) = 0 \quad (\text{A15})$$

$$C_\phi(k) = \text{Re} \{ \langle ik_z N_0 v_k \phi_k^* \rangle \} \quad (\text{A16})$$

$$D_\phi(k) = \text{Re} \left\{ \left\langle -\mu_\phi (\partial_r^2 \varpi_k + \frac{1}{r} \partial_r \varpi_k - \frac{m^2}{r^2} \varpi_k) \phi_k^* - \nu_{in} E_\phi(k) \right\rangle \right\} \quad (\text{A17})$$

$$T_\phi(k, k') = \text{Re} \left\{ \left\langle -\frac{1}{r} (im' \varpi_{k'} \partial_r \phi_{k-k'} \phi_k^* - i(m-m') \partial_r \varpi_{k'} \phi_{k-k'} \phi_k^*) \right\rangle \right\} \quad (\text{A18})$$

and for the electron temperature potential energy:

$$\frac{\partial E_t(k)}{\partial t} = Q_t(k) + C_t(k) + D_t(k) + \sum_{k'} T_t(k, k') \quad (\text{A19})$$

$$E_t(k) = \frac{3}{4} \langle |t_k|^2 \rangle \quad (\text{A20})$$

$$Q_t(k) = \text{Re} \left\{ \left\langle -\frac{3im}{2r} \partial_r T_{e0} \phi_k t_k^* \right\rangle \right\} \quad (\text{A21})$$

$$C_t(k) = \text{Re} \{ \langle -1.71 ik_z T_{e0} v_k t_k^* \rangle \} \quad (\text{A22})$$

$$D_t(k) = \text{Re} \left\{ \left\langle -\frac{\kappa_{||e}}{N_0} k_z^2 |t_k|^2 - \frac{3m_e}{m_i} \nu_e |t_k|^2 + \frac{3}{2} \mu_T (\partial_r^2 t_k + \frac{1}{r} \partial_r t_k - \frac{m^2}{r^2} t_k) t_k^* + \frac{3}{2} S_{Tk_z} t_{m=0, k_z}^* \right\rangle \right\} \quad (\text{A23})$$

$$T_t(k, k') = \text{Re} \left\{ \left\langle \frac{3}{2r} (im' t_{k'} \partial_r \phi_{k-k'} t_k^* - i(m-m') \partial_r t_{k'} \phi_{k-k'} t_k^*) \right\rangle \right\} \quad (\text{A24})$$

and for the parallel kinetic energy:

$$\frac{\partial E_v(k)}{\partial t} = Q_v(k) + C_v(k) + D_v(k) + \sum_{k'} T_v(k, k') \quad (\text{A25})$$

$$E_v(k) = \frac{1}{2} \frac{m_e}{m_i} \langle |v_k|^2 \rangle \quad (\text{A26})$$

$$Q_v(k) = \text{Re} \left\{ \left\langle ik_z \frac{N_0^2 - T_{e0}}{N_0} n_k v_k^* + ik_z (1 - N_0) \phi_k v_k^* + 1.71 ik_z (T_{e0} - 1) t_k v_k^* \right\rangle \right\} \quad (\text{A27})$$

$$C_v(k) = \text{Re} \{ \langle -ik_z N_0 n_k v_k^* + ik_z N_0 \phi_k v_k^* - 1.71 ik_z T_{e0} t_k v_k^* \rangle \} \quad (\text{A28})$$

$$D_v(k) = \text{Re} \left\{ \left\langle -\nu_e \frac{m_e}{m_i} |v_k|^2 \right\rangle \right\} \quad (\text{A29})$$

$$T_v(k, k') = \text{Re} \left\{ \frac{m_e}{m_i} \left\langle \frac{1}{r} (im' v_{k'} \partial_r \phi_{k-k'} v_k^* - i(m - m') \partial_r v_{k'} \phi_{k-k'} v_k^*) \right\rangle \right\} \quad (\text{A30})$$

The transfer channel $C_v(k)$ is specifically set so that $C_n(k) + C_t(k) + C_\phi(k) + C_v(k) = 0$. The source $Q_v(k)$ is the left over quantity, which can have any sign and contributes to the overall energy evolution.
